Abstract

We present results for two-loop QCD corrections to the short distance coefficient that governs leptonic decay of B_c-meson. After brief discussion of the technics of asymptotic expansion used to perform this calculation, we give comments on the numerical value of two-loop corrections and its impact on NRQCD description of B_c-meson bound state.

1 Introduction

The description of various aspects of B_c-meson physics[1] has received recently a lot of attention both from theoretical and experimental sides. B_c-meson is the only meson within SM, which contains two heavy quarks of different flavor. For this reason one might expect, that its spectroscopy, production mechanisms and decays differ significantly from those of charmonium, bottomonium as well as hadrons with one heavy quark. Indeed, contrary to the case of J/Ψ and Υ-mesons, B_c-meson is a long living system, decaying trough electroweak interactions. To produce $\bar{b}c$-system in flavor conserving collisions, an additional heavy quark pair should be created, what makes the consideration of production mechanism complex already at the leading order in the coupling constant. The bound state heavy quarks dynamics, being very similar to that of other quarkonia, at the same time has some differences. With respect to the hierarchy of dynamical scales, B_c-meson stands among the families of charmonium $\bar{c}c$ and bottomonium $\bar{b}b$ and thus could be used to study both quantitatively and conceptually existing effective low energy frameworks for the description of bound state heavy quark dynamics, like NRQCD [2], pNRQCD [3] and vNRQCD [4]. So, the study of B_c-meson gives us an opportunity to test SM in a completely new dynamical regime, explore it at a different angle, what may give us an additional insight into our understanding of SM in general.

Today, we already have many theoretical predictions, concerning various B_c-meson properties: spectroscopy [5], production [6] and decay channels [7]. In the present work we will be interested in radiative corrections to the leptonic decay constant of B_c-meson, entering expression for its purely leptonic width. This particular decay mode of B_c-meson is not really interesting for a direct measurement — the necessarily spin-flip makes its branching fraction very small. However, the same quantity appears in the formulation of two-point QCD sum rules [8]. And the latter may be used to extract an additional information about parameters of SM, namely the heavy quark masses. A first step towards systematic formulation of NNLO B_c-meson sum rules, treating B_c-meson as a Coulomb system, was made in [9], where NLO

[1] For a review see [1]

analysis was presented. In order to describe B_c-meson QCD sum rules at NNLO, one needs both 2-loop matching Wilson coefficient of QCD current with B_c quantum numbers on corresponding NRQCD current and two point NRQCD correlator, computed at NNLO. Below we will present the results of matching procedure. These results are also interesting from the point of view of further development of computation technics used in dimensionally regulated NRQCD [10]. Here we are dealing with threshold expansion with two mass scales m_b and m_c, what is an extension of previously obtained results for matching of vector current with two equal heavy quark masses [11, 12]. The presence of two mass scales of course makes problem more complicated, however as we will see the whole calculation could be performed within the general framework of threshold expansion in dimensionally regulated NRQCD [10]. Here we would like to stress, that we treat B_c-meson as a Coulomb system. So, in our matching procedure c-quark is considered to be heavy with respect to factorization scale $m_c > \mu_{\rm fac}$. As a consequence, it is impossible to make connection of our result with the results on the matching of heavy-light currents [13]. On the other side the limit $m_b = m_c$ is well defined in our approach and in the case of vector current matching with equal quark masses we reproduce already known results of [11, 12].

This paper is organized as follows. In section 2 we introduce necessary notation and present one-loop results obtained previously [14]. Section 3 contains two-loop results for B_c-meson leptonic decay constant. Here we also describe shortly various steps of the performed calculation. And finally, in section 4 we present our conclusion.

2 B_c - meson leptonic constant: one loop result

The B_c-meson leptonic decay proceeds through a virtual W-boson. The W-boson couples to the B_c through the axial-vector part of the charged weak current. All QCD effects, both perturbative and nonperturbative, enter into the decay rate through the decay constant f_{B_c}, defined by the matrix element

$$\langle 0|\bar{b}\gamma^\mu\gamma_5 c|B_c(P)\rangle \;=\; i f_{B_c} P^\mu, \tag{1}$$

where $|B_c(P)\rangle$ is the state of B_c-meson with four-momentum P. It has the standard covariant normalization $\langle B_c(P')|B_c(P)\rangle = (2\pi)^3 2E\,\delta^3(P'-P)$ and its phase has been chosen so that f_{B_c} is real and positive.

To separate short-distance ($\sim 1/m_Q$) and long-distance ($\gg 1/m_Q$) QCD contributions to f_{B_c} we use the formalism of NRQCD [2]. As a result the decay amplitude is factored into short-distance coefficients multiplied by NRQCD matrix elements. The Wilson short-distance coefficients could be then calculated further order by order in perturbation theory by matching a perturbative calculation in the full QCD with the corresponding perturbative calculation in NRQCD. It is the subject of this paper to calculate Wilson coefficient in front of NRQCD current up to 2-loop order in perturbative QCD.

Let us now discuss the matching procedure in some detail. We start with NRQCD lagrangian describing B_c-meson bound state dynamics

$$\mathcal{L}_{\rm NRQCD} \;=\; \mathcal{L}_{\rm light} \;+\; \psi_c^\dagger\left(iD_0 + \mathbf{D}^2/(2m_c)\right)\psi_c \;+\; \chi_b^\dagger\left(iD_0 - \mathbf{D}^2/(2m_b)\right)\chi_b \;+\; \ldots, \tag{2}$$

where $\mathcal{L}_{\rm light}$ is the usual relativistic lagrangian for gluons and light quarks. The 2-component field ψ_c annihilates charm quarks, while χ_b creates bottom antiquarks. The typical relative velocity v of heavy quarks inside the meson provides a small parameter that can be used as a nonperturbative expansion parameter.

To express the decay constant f_{B_c} in terms of NRQCD matrix elements, we express the axial-vector current $\bar{b}\gamma^\mu\gamma_5 c$ in terms of NRQCD fields. Only the $\mu = 0$ component contributes to the matrix element (1) in the rest frame of the B_c-meson. This component of the current has the following operator expansion in terms of NRQCD fields:

$$\bar{b}\gamma^0\gamma_5 c \;=\; C_0(m_b, m_c)\; \chi_b^\dagger \psi_c \;+\; C_2(m_b, m_c)\; (\mathbf{D}\chi_b)^\dagger \cdot \mathbf{D}\psi_c \;+\; \ldots, \tag{3}$$

where C_0 and C_2 are Wilson short-distance coefficients that depend on the quark masses m_b and m_c. By dimensional analysis, the coefficient C_2 is proportional to $1/m_Q^2$. The contribution to the matrix element $\langle 0|\bar{b}\gamma^0\gamma_5 c|B_c\rangle$ from the operator $(\mathbf{D}\chi_b)^\dagger \cdot \mathbf{D}\psi_c$ is suppressed by v^2 relative to the operator $\chi_b^\dagger\psi_c$, where v is the relative velocity of heavy quarks inside B_c-meson. The dots in (3) represent other operators whose contributions are suppressed by higher powers of v^2.

The short-distance coefficient C_0 and C_2 can be determined by matching perturbative calculations of the matrix elements in the full QCD and NRQCD. A convenient choice for matching is the matrix element between the vacuum and the state $|c\bar{b}\rangle$ consisting of a c and a $\bar{b}$ on their perturbative mass shells with nonrelativistic four-momenta p and p' in the center of momentum frame: $\mathbf{p} + \mathbf{p}' = 0$. The matching condition is

$$\langle 0|\bar{b}\gamma^0\gamma_5 c|c\bar{b}\rangle\Big|_{\rm QCD} = C_0\; \langle 0|\chi_b^\dagger\psi_c|c\bar{b}\rangle\Big|_{\rm NRQCD} \;+\; C_2\; \langle 0|(\mathbf{D}\chi_b)^\dagger \cdot \mathbf{D}\psi_c|c\bar{b}\rangle\Big|_{\rm NRQCD} \;+\; \ldots, \tag{4}$$

where QCD and NRQCD represent perturbative QCD and perturbative NRQCD, respectively. At leading order in α_s, the matrix element on the left hand side of (4) is $\bar{v}_b(-\mathbf{p})\gamma^0\gamma_5 u_c(\mathbf{p})$. The Dirac spinors are

$$u_c(\mathbf{p}) \;=\; \sqrt{\frac{E_c + m_c}{2E_c}} \begin{pmatrix} \xi \\ \frac{\mathbf{p}\cdot\boldsymbol{\sigma}}{E_c + m_c}\xi \end{pmatrix}, \tag{5}$$

$$v(-\mathbf{p}) \;=\; \sqrt{\frac{E_b + m_b}{2E_b}} \begin{pmatrix} \frac{(-\mathbf{p})\cdot\boldsymbol{\sigma}}{E_b + m_b}\eta \\ \eta \end{pmatrix}, \tag{6}$$

where ξ and η are 2-component spinors and $E_Q = m_Q^2 + \mathbf{p}^2$. Making a nonrelativistic expansion of the spinors to second order in $\mathbf{p}/m_Q$, we find

$$\bar{v}_b(-\mathbf{p})\gamma^0\gamma_5 u_c(\mathbf{p}) \;\approx\; \eta_b^\dagger \xi_c \left(1 \;-\; \frac{1}{8}\left(\frac{m_b + m_c}{m_b m_c}\right)^2 \mathbf{p}^2 \;+\; \ldots\right). \tag{7}$$

At leading order in α_s, the matrix elements on the right hand side of (4) are $\eta_b^\dagger\xi_c$ and $\mathbf{p}^2\eta_b^\dagger\xi_c$. The short distance coefficients are therefore $C_0 = 1$ and

$$C_2 \;=\; -\frac{1}{8\, m_{\rm red}^2}, \tag{8}$$

where $m_{\rm red} = m_b m_c/(m_b + m_c)$ is the reduced mass of the system.

In order to determine the short distance coefficients up to order α_s^2, we must calculate the matrix elements on both sides of (4) up to α_s^2. Up to this order it is sufficient to calculate radiative corrections only for the coefficient C_0, since the contribution proportional to C_2 is suppressed by additional power of v^2. The coefficient C_0 can be isolated by taking the limit

$\mathbf{p} \to 0$, in which case the matrix element of $(\mathbf{D}\chi_b)^\dagger \cdot \mathbf{D}\psi_c$ vanishes. Such calculation at the one-loop order was performed in [14], where the following result was obtained for C_0:

$$C_0 \;=\; 1 \;+\; \frac{\alpha_s(m_{\rm red})}{\pi}\left[\frac{m_b - m_c}{m_b + m_c}\log\frac{m_b}{m_c} - 2\right]. \tag{9}$$

$m_{\rm red}$ is the scale of the running coupling constant. To the accuracy of this calculation, any scale of order m_b or m_c would be equally correct.

Thus, the final result for the decay constant of the B_c is

$$if_{B_c}M_{B_c} \;=\; C_0\,\langle 0|\chi_b^\dagger\psi_c|B_c\rangle \;+\; C_2\,\langle 0|(\mathbf{D}\chi_b)^\dagger\cdot\mathbf{D}\psi_c|B_c\rangle. \tag{10}$$

with short-distance coefficient C_0 up to next-to-leading order in α_s as given in (9), while C_2 is given to leading order in (8). The uncertainties consist of the perturbative errors in the short distance coefficients and an error of relative order v^4 from the neglected matrix elements that are higher order in v^2. The matrix element $\langle 0|\chi_b^\dagger\psi_c|B_c\rangle$ can be estimated using wavefunctions at the origin from nonrelativistic potential models:

$$|\langle 0|\chi_b^\dagger\psi_c|B_c\rangle|^2 \;\approx\; 2M_{B_c}\frac{3}{2\pi}|R(0)|^2. \tag{11}$$

The factor of $2M_{B_c}$ takes into account the relativistic normalization of the state $|B_c\rangle$.

3 Two-loop result

In this section we consider the two-loop contribution to B_c-meson leptonic constant. An analogous calculation, but for the case of vector current and equal quark masses was done previously in [11, 12]. Here we are following the approach of [11, 12], extending it, where it is necessary, to the case of two different mass scales involved in our problem. In the case of B_c-meson we consider the matching of QCD axial current on the NRQCD one.

To compute Wilson short distance coefficient C_0 up to α_s^2 order, we replace B_c-meson state by a free quark-antiquark pair of on-shell heavy quarks with small relative velocity. In terms of the on-shell matrix elements for heavy quarks with small relative velocity: $p = qm_1/(m_1+m_2)$ and $p' = qm_2/(m_1+m_2)$ (q is the momentum of the gauge W-boson) [2]. The matching equation has the following form

$$Z_{2,QCD}\Gamma_{QCD} = C_0 Z_{2,\rm NRQCD} Z^{-1}_{J,\rm NRQCD}\Gamma_{\rm NRQCD} + O(v^2), \tag{12}$$

where $\Gamma_{\rm QCD}$ and $\Gamma_{\rm NRQCD}$ are amputated bare axial-vector vertices in QCD and NRQCD, correspondingly. Here, we would like to note, that since terms of order v^2 are not needed to determine C_0 (see Eq. (4)), one can set relative momentum to zero and compute Green functions directly at the threshold. Note, that here we deal with partially conserved axial-vector current and its QCD renormalization constant is given by $Z_{J,\rm QCD} = 1$, as in the case of vector current.

In order to obtain the coefficient C_0 at two loops one has to perform the following steps:

1) sum over all contributions to Γ's, including the one-loop term, multiplied by the two-loop QCD on-shell wave function renormalization constant [15], $Z^{-1}_{J,\rm QCD}$ and one-loop NRQCD-current renormalization constant (at one-loop it is equal to unity),

[2] This and previous definitions of external heavy quark momenta lead to the same value of the matching coefficient, but latter is more convenient in two-loop calculations.

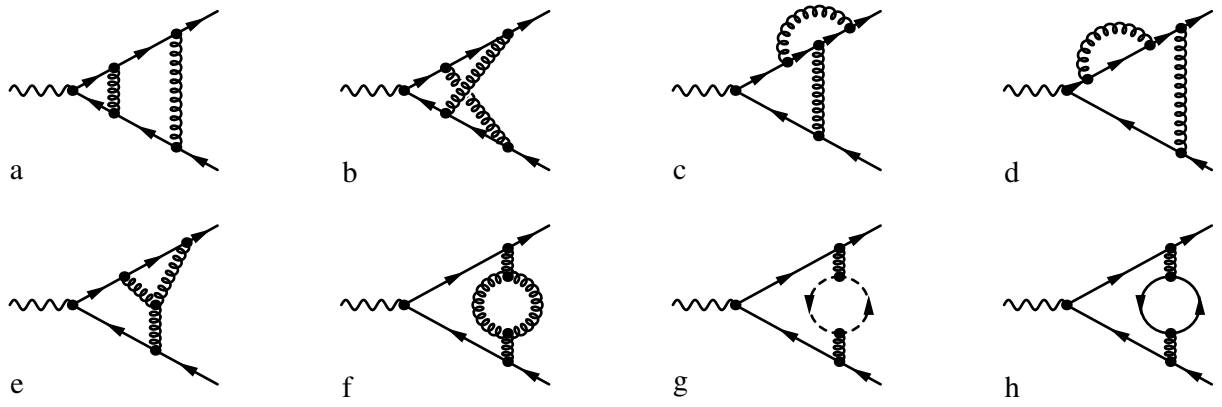

Figure 1: QCD Feynman diagrams relevant for the calculation of the two-loop corrections to the B_c structure constant.

2) perform the one-loop renormalization of the coupling and masses.

After these manipulations the remaining poles in ϵ belong to the anomalous dimension of the corresponding NRQCD current and finite part correspond to short-distance constant C_0.

In step 1) calculating two-loop contribution to vector-axial vertex, it is convenient to write it in the following form

$$A_\mu = \bar{b}(p')\Big[\gamma_\mu\gamma_5 F_1(q^2) - \frac{1}{m_1+m_2} q_\mu\gamma_5 F_4(q^2)\Big]c(p)\,. \tag{13}$$

The formfactors $F_1(q^2)$ and $F_2(q^2)$ can be singled out by imposing appropriate projections on them and thus our calculation will reduce to the calculation of diagrams with nonvanishing numerators.

To simplify matching calculation at 2-loop order we use threshold expansion in relative velocity v of [10]. The latter is obtained by writing down contributions corresponding to hard ($k \sim m_Q$), soft ($k \sim m_Q v$), potential ($k_0 \sim m_Q v^2, k_i \sim m_Q v$) and ultrasoft ($k \sim m_Q v^2$) regions[3]. The contributions from the last three regions can be easily identified with NRQCD diagrams, that appear in the calculation of $\Gamma_{\rm NRQCD}$. Thus, they simply drop out from the matching relation (12) and it will suffice to compute only contribution to threshold expansion of $\Gamma_{\rm QCD}$ of the region, where all momenta are hard. Diagrams, whose hard contribution need to be computed, are depicted in Fig. 1. Both form factors, introduced above have Coulomb singularities at the threshold and diverge as $1/v^2$. However, these singularities appear only in the soft, potential and ultrasoft contributions, while the hard contribution is well defined in dimensional regularization directly at the threshold. Once the relative velocity is set to zero, the corresponding loop integrals are considerably simplified and depend only on two scales M and m, where M is the mass of the heaviest quark and m is the mass of the lighter quark. All loop integrals with irreducible numerators can then be further reduced to the scalar integrals with increased space-time dimension [16]. For the scalar integrals we derived recurrence relations using integration by parts method of [17], which allowed us to reduce all scalar integrals to sunsets. The sunset integrals obtained were further reduced to master integrals with the use

[3]Here k is the integration momentum.

of recurrence relations of [18, 19, 20, 21]. We would like to note, that our reduction procedure is valid for arbitrary values of heavy quark masses, while to calculate some master integrals an expansion in parameter $r = m/M$ was performed. All master integrals are of the sunset type discussed in the paper [21]. In particular there we discuss in full details the procedure of expansion in parameter r. Here, we describe only shortly the calculation procedure and more detailed exposition will be given elsewhere. The results, obtained for each of diagrams in Fig. 1 could be found in Appendix A.

After performing the steps of renormalization procedure described above, we have the following $\overline{\rm MS}$ expression for the anomalous dimension of NRQCR current, which first arises here at the two-loop order ($r = m/M$)

$$\gamma_{J,\rm NRQCD} = \frac{d \ln Z_{J,\rm NRQCD}}{d \ln \mu} = -\left\{ C_F^2 \left(2 - \frac{(1-r)^2}{(1+r)^2} \right) + C_F C_A \right\} \frac{\pi^2}{2} \left(\frac{\alpha_s}{\pi} \right)^2 + \mathcal{O}(\alpha_s^3). \quad (14)$$

This scale dependence is compensated by the scale dependence of the two-loop matching coefficient $c_2(M/\mu)$, which is defined as

$$C_0(\alpha_s, \frac{M}{\mu}) = 1 + c_1(M/\mu) \frac{\alpha_s(M)}{\pi} + c_2(M/\mu) \left(\frac{\alpha_s(M)}{\pi} \right)^2 + \ldots, \quad (15)$$

In order to obtain c_2 in analytical form, we perform the expansion of master integrals, considering the parameter $r = m/M$ as small (in the practice $r = m_c/m_b \sim 0.3$). Below we give the result of expansion up to $O(r^2)$ inclusive. Separating the different colour group factors, in $c_2(M/\mu)$ in the $\overline{\rm MS}$ we have:

$$c_2(M/\mu) = C_F^2 c_{2,A} + C_F C_A c_{2,NA} + C_F T_F n_l c_{2,L} + C_F T_F c_{2,H}, \quad (16)$$

$$c_{2,A} = \left(2 - \frac{(1-r)^2}{(1+r)^2} \right) \frac{\pi^2}{4} \ln\left(\frac{M^2}{\mu^2} \right) + \frac{9}{32} L^2 + \frac{\pi^2}{3} L + \frac{41}{32} L + \pi^2 \ln(2) - \frac{91\pi^2}{48} + \frac{29}{16}$$
$$+ r \left[\frac{17\pi^2}{12} L - \frac{43}{16} L - 6\zeta_3 + \frac{23\pi^2}{24} - \frac{3}{8} \right] + r^2 \left[-\frac{21}{8} L^2 - 3\pi^2 L + \frac{165}{16} L + 12\zeta_3 - \frac{25\pi^2}{12} - \frac{147}{16} \right], \quad (17)$$

$$c_{2,NA} = \frac{\pi^2}{4} \ln\left(\frac{M^2}{\mu^2} \right) + \frac{11}{16} L^2 + \frac{13\pi^2}{24} L + \frac{127}{96} L - \frac{9}{4} \zeta_3 - \frac{1}{2} \pi^2 \ln(2) + \frac{41\pi^2}{96} - \frac{23}{48}$$
$$+ r \left[-\frac{25}{16} L^2 - \frac{\pi^2}{24} L + \frac{65}{48} L - \frac{2\pi^2}{3} - \frac{49}{32} \right] + r^2 \left[\frac{15}{8} L^2 - \frac{23}{16} L + \frac{19\pi^2}{48} + \frac{31}{36} \right], \quad (18)$$

$$c_{2,L} = -\frac{1}{4} L^2 - \frac{11}{24} L + \frac{5\pi^2}{144} + \frac{1}{12} + r \left[\frac{L^2}{2} - \frac{L}{12} \right] + r^2 \left[\frac{L}{12} - \frac{L^2}{2} \right], \quad (19)$$

$$c_{2,H} = -\frac{L^2}{4} - \frac{11L}{24} - \frac{19\pi^2}{96} + \frac{1147}{288} + r \left[\frac{L^2}{2} - \frac{L}{12} - \frac{23\pi^2}{96} - \frac{103}{144} \right]$$
$$+ r^2 \left[-\frac{L^2}{2} + \frac{89L}{60} + \frac{23\pi^2}{96} + \frac{11527}{3600} \right]. \quad (20)$$

Here $\zeta_3 = 1.202\ldots$, $M = m_b$, $r = m_c/m_b$, $L \equiv \ln(r)$ and we have taken all fermions with masses less than m_b and m_c as massless. The heavy quark masses, appearing in our formulae

are pole quark masses. All calculations were performed with the help of computer algebra system FORM [22]. As a check for our calculations, we employed a general covariant gauge. To test our FORM programs we also have reproduced already known results for the sort distance corrections to the vector current with equal masses.

Now let us discuss the expression for 2-loop anomalous dimension of B_c-meson NRQCD current. It is an exact formula in a sense, that we resumed a whole series in r. In the limit of equal quark masses it differs from the result obtained in the case of vector current. This fact is explained by the contribution, coming from Breit–Fermi potential, namely spin-spin and spin-orbital heavy quark interaction, which in the case of B_c-meson has a different expression compared to that computed for J/Ψ and Υ-mesons [23]. This result for anomalous expression could be also obtained considering NNLO corrections to the Coulomb Green function, given by Breit–Fermi and non-abelian potentials.

Numerically, the scale dependence of the two-loop matching coefficient (16) is large. We expect it to be compensated by the scale dependence of B_c-meson wave function computed within the lattice NRQCD framework with the scale dependence of the results introduced by imposing ultraviolet cutoff/factorization scale. The results of nonrelativistic potential models should be considered as being obtained at a scale typical for B_c-meson bound state dynamics $\mu \sim 1$ GeV. For numerical estimates we consider $\mu = 1$ GeV as an adequate bound state scale and use its value for factorization scale $\mu_{\rm fac}$. In the case of B_c-meson and pole quark masses ($m_b = 4.8$ GeV, $m_c = 1.65$ GeV) we have

$$f_{B_c} = \left[1 - 1.48\left(\frac{\alpha_s(m_b)}{\pi}\right) - 24.24\left(\frac{\alpha_s(m_b)}{\pi}\right)^2\right] f_{B_c}^{NR} \tag{21}$$

Here we see that 2-loop corrections are large and constitute $\approx 100\%$ of 1-loop correction. Even less favorable situation was detected earlier for J/Ψ states [11]. The variation of factorization scale does not help to solve this problem. So, at this point one may conclude that application of NRQCD to B_c-meson as well as for J/Ψ is not well justified. However, while in the case of J/Ψ-meson 2-loop corrections far exceed 1-loop, one may speculate that situation in B_c-meson is marginal, in a sense that one may still obtain sensible results using NRQCD framework as well as treating B_c-meson as a heavy-light system. This way one may study the change in heavy quarks dynamics between bottomonium and charmonium families. Another possible reason for such large correction is our use of particular renormalization scheme $\overline{\rm MS}$, which may turn out not to work well for heavy quark bound state systems. To prove or disprove this statement one has to calculate 2-loop corrections to any relation between physical observables, from which quarkonium wave function at the origin is eliminated [11].

4 Conclusion

In this paper we presented the results for the two-loop radiative corrections to the short distance coefficient in matching between QCD and NRQCD for the B_c-meson currents. It turns out that the numerical value of these corrections are large. There are several conclusions, which could be made here. First NRQCD description is inadequate not only for charmonium family but also for B_c-meson. To see whether it is true, we suppose to perform a systematical study of NRQCD B_c-meson sum rules at NNLO in one of our next publications. Second, is it the use of $\overline{\rm MS}$ renormalization scheme, which makes things look nasty?. To answer this question one needs to compute some other decay mode of either J/Ψ or B_c -mesons at 2-loop level and analyze perturbative corrections to the ratio of these decay modes.

We thank K. Chetyrkin, A. Davydychev, A. Grozin, M. Kalmykov, V. Kiselev, O. Tarasov and A. Pivovarov for fruitful discussion of the topics discussed in this paper. We especially grateful to V. Smirnov for encouragement, constant interest to this work and help with numerous checks of our calculation. This work was supported by DFG Forschergruppe "Quantenfeldtheorie, Computeralgebra and Monte-Carlo-Simulation" (contract FOR 264/2-1) and by BMBF under grant No 05HT9VKB0.

A 2 loop bare hard contribution

Here we collected results for hard contributions of diagrams, shown in Fig. 1. Below, to save space, we present only coefficient of $(\alpha_s/\pi)^2 (e^{\gamma_E} M^2/(4\pi\mu^2))^{-2\varepsilon}$ for each of the digrams, presented above. Though our calculations were performed in general covariant gauge, we present here for brevity only the results in the Feynman gauge.
